1 Introduction

In a two-country model, an import tariff appreciates the tariffing country's currency under the Marshall–Lerner condition. In a multilateral setting, a discriminatory tariff also shifts expenditure across foreign suppliers. As a result, the tariffing country's bilateral exchange rates need not all move in the same direction.

These notes characterize the exchange-rate effects of tariffs in an N -country model. The general log-linearized equilibrium response is $(-J)^{-1}F$, where F is the vector of trade-balance disturbances created by the tariff at unchanged exchange rates and J is the Jacobian of trade balances with respect to exchange rates. Under symmetry and a multilateral Marshall–Lerner condition on J , the tariffing country always appreciates against the target, but its bilateral response against an untariffed bystander is ambiguous and depends on whether the cross-origin elasticity of substitution across foreign imported tradables exceeds the threshold $N\rho_1^*$. The factor N in this threshold is a property of adjustment rather than of impact: the relative size of the two trade-balance disturbances does not depend on N , but exchange-rate adjustment absorbs a zero-sum disturbance across partners N times faster than a uniform one.

Despite this bilateral ambiguity, the tariffing country's nominal effective exchange rate (NEER) appreciates for every admissible cross-origin elasticity and every N . The specific form of the NEER derives from our symmetric nested-CES model, but the underlying distinction between aggregate home-versus-foreign adjustment and reallocation across foreign suppliers is more general: under symmetry any tariff vector imposed by the tariffing country splits into a scale component, which alone determines the effective rate, and a discriminatory component, which alone determines the distribution of bilateral rates around it, and the two results are the two components of this decomposition (Section 6.2). Proofs of all formal results are collected in Appendix D.

2 N -Country Model and Equilibrium

2.1 Production and preferences

Countries are indexed by $i, j \in \{1, \dots, N\}$. We use A for the tariff imposer, B for the tariff target, and C for an untariffed bystander. Each country produces a country-specific tradable and a non-tradable from labor:

$$Y_{T_i} = A_{T_i} L_{T_i}, \quad Y_{N_i} = A_{N_i} L_{N_i}, \quad L_{T_i} + L_{N_i} = L_i, \quad (1)$$

with perfect competition and producer-price normalization $P_{T_i} = 1$ in i 's currency, so

$$w_i = A_{T_i}, \quad P_{N_i} = A_{T_i}/A_{N_i}. \quad (2)$$

Wages are constant in own currency, so relative adjustment occurs through exchange rates. Preferences are nested CES with share-linear weights:

$$C_i = C_{T_i}^{\alpha_T} C_{N_i}^{1-\alpha_T} \quad (\text{tradable share } \alpha_T) \quad (3)$$

$$C_{T_i} = \left[\alpha_D^{1/\eta} C_{T_{ii}}^{\frac{\eta-1}{\eta}} + (1 - \alpha_D)^{1/\eta} M_i^{\frac{\eta-1}{\eta}} \right]^{\frac{\eta}{\eta-1}} \quad (\text{home weight } \alpha_D, \text{ elasticity } \eta) \quad (4)$$

$$M_i = \left[\sum_{j \neq i} \beta_{ij}^{1/\rho} C_{T_{ji}}^{\frac{\rho-1}{\rho}} \right]^{\frac{\rho}{\rho-1}} \quad (\text{origin weights } \beta_{ij}, \text{ elasticity } \rho). \quad (5)$$

The elasticity η governs substitution between domestic and imported tradables, while ρ governs substitution across foreign origins conditional on importing. The latter margin is inactive at $N = 2$ and active at $N \geq 3$.

The *symmetric benchmark* imposes $\beta_{ij} = 1/(N - 1)$, common parameters $(\alpha_T, \alpha_D, \eta, \rho)$, and equal endowments and productivities. Home bias α_D preserves an asymmetry between home and foreign tradables. Full symmetry between home and foreign tradables would additionally require $\rho = \eta$ and $\alpha_D = 1/N$, which we do not impose.

2.2 Tariffs, prices, income, and trade balance

Tariffs $\tau_{ij} \geq 0$ are ad valorem and are levied by i on imports from j , with $\tau_{ii} = 0$. Consumer prices in i 's currency are $p_{ij} = (1 + \tau_{ij}) e_{ij}$ and $p_{ii} = 1$. The corresponding price indices are

$$P_{M_i} = \left[\sum_{j \neq i} \beta_{ij} p_{ij}^{1-\rho} \right]^{\frac{1}{1-\rho}}, \quad P_{T_i} = \left[\alpha_D p_{ii}^{1-\eta} + (1 - \alpha_D) P_{M_i}^{1-\eta} \right]^{\frac{1}{1-\eta}}, \quad P_i = \kappa_i P_{T_i}^{\alpha_T} P_{N_i}^{1-\alpha_T}. \quad (6)$$

Expenditure shares of income are

$$s_{ii} = \alpha_T \alpha_D \left(\frac{p_{ii}}{P_{T_i}} \right)^{1-\eta}, \quad s_{ij} = \alpha_T (1 - \alpha_D) \left(\frac{P_{M_i}}{P_{T_i}} \right)^{1-\eta} \beta_{ij} \left(\frac{p_{ij}}{P_{M_i}} \right)^{1-\rho}, \quad j \neq i, \quad (7)$$

so $s_{ij} I_i$ is tariff-inclusive spending at consumer prices and $s_{ij} I_i / (1 + \tau_{ij})$ is the tariff-exclusive border value. Tariff revenue is rebated lump-sum:

$$I_i = w_i L_i + \sum_{j \neq i} \frac{\tau_{ij}}{1 + \tau_{ij}} s_{ij} I_i \implies I_i = \frac{w_i L_i}{1 - \sum_{j \neq i} \frac{\tau_{ij}}{1 + \tau_{ij}} s_{ij}}. \quad (8)$$

Equation (8) determines income in i 's own currency. To add bilateral flows across countries, we express them in a common currency. Taking A 's currency as the numeraire, define common-

currency income as $\tilde{I}_i \equiv e_{Ai} I_i$. Expenditure shares are ratios of same-currency values and are therefore unchanged by this conversion. Since the tariff wedge is a domestic transfer, trade balances are valued at producer prices in the common currency:

$$\text{TB}_i = \sum_{k \neq i} f_{ki} - \sum_{j \neq i} f_{ij}, \quad f_{ij} \equiv \frac{s_{ij} \tilde{I}_i}{1 + \tau_{ij}}, \quad (9)$$

where f_{ij} is the border value, in A 's currency, of i 's imports from j .

By Walras' law, only $N - 1$ trade-balance conditions are independent. We also assume no internationally traded assets, so $\text{TB}_i = 0$ for all i . Given $\{\tau_{ij}\}$, the $N - 1$ free exchange rates therefore solve $\text{TB}_i = 0$ for $i \neq A$.

2.3 Exchange-rate concepts

Define e_{ij} as units of i 's currency per unit of j 's, with $e_{ii} = 1$ and $e_{ij} = e_{ik} e_{kj}$. A rise in e_{ij} therefore represents a depreciation of i against j . Log changes in bilateral exchange rates relative to A are denoted by $\nu_j \equiv d \log e_{Aj}$, with $\nu_A = 0$. Relative wages, terms of trade, real exchange rates, and effective exchange rates are defined as

$$\omega_{ij} \equiv \frac{e_{ij} w_j}{w_i}, \quad \text{ToT}_{ij} \equiv \frac{P_{T_i}}{e_{ij} P_{T_j}} = \frac{1}{e_{ij}}, \quad q_{ij} \equiv \frac{e_{ij} P_j}{P_i}, \quad (10)$$

$$d\nu_i^E \equiv \sum_{j \neq i} w_{ij} d \log e_{ij}, \quad dq_i^E \equiv \sum_{j \neq i} w_{ij} d \log q_{ij}, \quad w_{ij} = \frac{f_{ij} + f_{ji}}{\sum_{k \neq i} (f_{ik} + f_{ki})}, \quad (11)$$

with $w_{ij} = 1/(N - 1)$ in the symmetric model. Under the production normalization,

$$d \log e_{ij} = d \log \omega_{ij} = -d \log \text{ToT}_{ij}, \quad (12)$$

so the nominal exchange-rate results can equivalently be expressed in terms of relative wages or terms of trade.

3 Two Countries

We begin with the symmetric two-country benchmark, where the equilibrium condition is a single scalar equation and the exchange-rate response can be read against the textbook elasticity condition. The general linearization for N countries is given in Section 5.1; here we need only its $N = 2$ case. Write $m \equiv \alpha_T(1 - \alpha_D)$ for the import share of income, so that $s_{AB} = s_{BA} = m$ at the balanced free-trade baseline with normalized incomes, and let $\nu_B \equiv d \log e_{AB}$. Suppose A imposes $d\tau = dt_{AB}$. Each country has a single import origin, so $dp_{AB} = d \log P_{M_A} = \nu_B + d\tau$ and $dp_{BA} = d \log P_{M_B} = -\nu_B$, and the cross-origin margin in (7) is inactive. Log-differentiating (7) and (8), with incomes in the common currency,

$$d \log s_{AB} = (1 - \eta) \alpha_D (\nu_B + d\tau), \quad d \log s_{BA} = -(1 - \eta) \alpha_D \nu_B, \quad d \log \tilde{I}_A = m d\tau, \quad d \log \tilde{I}_B = \nu_B.$$

Substituting into (9) and using that the tariff wedge lowers the border value of A 's imports by $d\tau$,

$$dTB_A = m[d \log s_{BA} + \nu_B] - m[d \log s_{AB} + m d\tau - d\tau] = m[(1 + 2\alpha_D(\eta - 1))\nu_B + (1 - m + \alpha_D(\eta - 1))d\tau].$$

Define

$$\rho_1^* \equiv 1 + \alpha_D(\eta - 1) - \alpha_T(1 - \alpha_D) = \underbrace{\alpha_D \eta}_{\text{home switching}} + \underbrace{(1 - \alpha_D)(1 - \alpha_T)}_{\text{expenditure absorption}} > 0. \quad (13)$$

The equilibrium condition then collects into an adjustment term and an impact term,

$$dTB_A = \underbrace{m D_2 \nu_B}_{\text{adjustment}} + \underbrace{m \rho_1^* d\tau}_{\text{impact disturbance}} = 0, \quad D_2 \equiv 2\alpha_D(\eta - 1) + 1, \quad (14)$$

and therefore

$$\boxed{\left. \frac{d \log e_{AB}}{d\tau} \right|_{\tau=0} = -\frac{\rho_1^*}{D_2}} \quad (15)$$

The impact term ρ_1^* combines substitution toward A 's own tradable and expenditure absorption outside the imported-tradables margin, both of which move A toward surplus at unchanged exchange rates. The cross-origin elasticity ρ plays no role at $N = 2$. It returns at $N \geq 3$ as the strength of foreign-supplier diversion, and the thresholds derived there compare ρ with the opposing forces collected in ρ_1^* .

In reduced form, let export volume be $X(1/e)$ and import volume be $M((1 + \tau)e)$, with elasticities ε_X and ε_M . Balanced trade gives $\partial TB_A / \partial e = M(\varepsilon_X + \varepsilon_M - 1)$. Comparing this expression with (14) per unit of import value gives

$$\varepsilon_X + \varepsilon_M - 1 = D_2, \quad \varepsilon_X = \varepsilon_M = \alpha_D(\eta - 1) + 1. \quad (16)$$

Proposition 3.1 (Conventional wisdom, $N = 2$). *At $N = 2$, exchange-rate adjustment stabilizes the trade balance if and only if $D_2 > 0$, which is exactly the textbook Marshall–Lerner condition $\varepsilon_X + \varepsilon_M > 1$. In our nested-CES model, it holds whenever $\eta \geq 1$. In the convention of (17), which uses B 's trade balance, the adjustment coefficient is $-J = mD_2$ and the impact disturbance is $F = -m\rho_1^* < 0$ for all admissible parameters, so a unilateral import tariff appreciates the tariffing country's currency: $d \log e_{AB} / d\tau = -\rho_1^* / D_2 < 0$.*

Appendix A gives the exact finite-tariff Cobb–Douglas solution. The condition $D_2 > 0$ is the scalar case of the multilateral condition introduced next.

4 From Two to N Countries: General Exchange-Rate Adjustments

The following results require only that trade balances are differentiable with respect to exchange rates and tariffs. They do not depend on the nested-CES structure of our model.

4.1 The local disturbance–adjustment representation

Consider any differentiable multilateral trade environment with $N - 1$ independent trade-balance conditions, $TB_i = 0$ for $i \neq A$, as functions of exchange rates and tariffs. Stack the exchange-rate changes as $d\nu \equiv (\nu_j)_{j \neq A}$ and the bilateral tariff changes as the vector $d\tau \equiv (dt_{jk})_{j \neq k}$. The conditions for $i \neq A$ are

$$J d\nu + G d\tau = 0, \quad J_{il} \equiv \frac{\partial dTB_i}{\partial \nu_l}, \quad G_{i,(jk)} \equiv \frac{\partial dTB_i}{\partial dt_{jk}} \Big|_{\nu \text{ fixed}}. \quad (17)$$

For a particular tariff experiment, write the tariff vector as $d\tau = a d\tau$, where a is a fixed direction vector and $d\tau$ is the scalar size of the tariff change. Defining the impact vector $F \equiv Ga$, the equilibrium conditions become

$$J d\nu = -F d\tau, \quad \frac{d\nu}{d\tau} = (-J)^{-1} F. \quad (18)$$

F gives the trade-balance effects of the tariff at unchanged exchange rates, including substitution and income effects, while J describes how trade balances respond to exchange-rate changes. The equilibrium response $(-J)^{-1} F$ combines these initial disturbances through the exchange-rate adjustment mechanism. At $N = 2$, $J = -mD_2$ and $F = m\rho_1^*$ in (14).

4.2 The multilateral Marshall–Lerner condition

Two structural identities restrict $\tilde{J}$, the full $N \times N$ Jacobian before country A is dropped. First, each trade balance is homogeneous of degree one in currency values. By Euler’s theorem, the log-derivatives in row i sum to TB_i , which is zero at a balanced baseline. The rows of $\tilde{J}$ therefore sum to zero. Second, Walras’ law gives $\sum_i TB_i \equiv 0$, so the columns also sum to zero. Thus,

$$\sum_l \tilde{J}_{il} = 0 \quad \forall i, \quad \sum_i \tilde{J}_{il} = 0 \quad \forall l. \quad (19)$$

At $N = 2$, the requirement that exchange-rate adjustment stabilizes the trade balance is the scalar condition $-J = mD_2 > 0$ of Section 3. The N -country generalization requires that the adjustment mapping $(-J)^{-1}$ be well defined and positive.

Definition 4.1 (Multilateral Marshall–Lerner condition). *The adjustment mechanism satisfies the multilateral Marshall–Lerner condition if*

$$-J \text{ is a nonsingular } M\text{-matrix:} \quad J_{il} \geq 0 \quad (l \neq i) \quad \text{and} \quad (-J)^{-1} \text{ exists with } (-J)^{-1} \geq 0. \quad (20)$$

By (18), each equilibrium exchange-rate response is a nonnegative-weighted combination of the initial trade-balance disturbances. If the components of F have the same sign, a nonnegative $(-J)^{-1}$ cannot produce responses of the opposite sign. Opposite-signed equilibrium responses therefore

require a mixed-sign F . When F has mixed signs, the sign of an individual response depends on a weighted combination of the entire disturbance vector, not simply on the corresponding F_i . The condition also implies $\det(-J) > 0$, which we use in the threshold calculations below.¹ At $N = 2$, the system is scalar and the condition reduces to $D_2 > 0$, which Section 3 showed to be the textbook elasticity condition.

A sufficient condition for the multilateral Marshall–Lerner condition is gross substitutability in the full Jacobian.

Assumption 1 (Gross substitutability). $\tilde{J}_{il} \geq 0$ for all $l \neq i$.

In the coordinates $\nu_l = d \log e_{Al}$, a rise in ν_l is an appreciation of currency l against the numeraire. Gross substitutability therefore requires that one country’s appreciation does not worsen another country’s trade balance. Together with (19), this implies adverse own effects and weak diagonal dominance, which deliver the M-matrix property under the conditions below.

Proposition 4.2 (Sufficiency of gross substitutability). *Under Assumption 1, with J irreducible and $\tilde{J}_{iA} > 0$ for some i , the multilateral Marshall–Lerner condition (20) holds.*

The diagonal-dominance calculation and the remaining M-matrix arguments are in Appendix D. Gross substitutability restricts the local effects in J , while the multilateral Marshall–Lerner condition restricts the equilibrium adjustment mapping $(-J)^{-1}$. The results below require only the latter. Its implication for signs can be stated directly.

Corollary 4.3 (Sign rule). *Under (20),*

$$\text{sign}\left(\frac{d\nu_i}{d\tau}\right) = \text{sign}\left(\sum_j \vartheta_{ij} F_j\right), \quad \vartheta_{ij} \equiv [(-J)^{-1}]_{ij} \geq 0. \quad (21)$$

4.3 Exchangeable partners

Restrict attention to tariffs imposed by A , $t \equiv (t_j)_{j \neq A}$ with $t_j \equiv dt_{Aj}$, so that G in (17) becomes an $(N - 1) \times (N - 1)$ matrix over A ’s partners. We say that the partners are *exchangeable* if the reduced linear system is invariant to relabeling them, $PJP' = J$ and $PGP' = G$ for every permutation matrix P of the $N - 1$ partners. This is a hypothesis on the linearized system at the baseline, weaker than the full symmetric benchmark of Section 2, and it requires nothing of the demand system beyond differentiability.

Lemma 4.4 (Exchangeable partners). *If the partners are exchangeable, then $-J = a_J I + b_J \mathbf{1}\mathbf{1}'$ and $G = a_G I + b_G \mathbf{1}\mathbf{1}'$ for scalars (a_J, b_J, a_G, b_G) . Both matrices have the constant vector $\mathbf{1}$ and its zero-sum complement $\{v : \mathbf{1}'v = 0\}$ as eigenspaces, with eigenvalues*

$$j_S \equiv a_J + (N - 1)b_J, \quad j_D \equiv a_J \quad \text{for } -J; \quad g_S \equiv a_G + (N - 1)b_G, \quad g_D \equiv a_G \quad \text{for } G. \quad (22)$$

¹Given the Z-matrix sign pattern, the condition is further equivalent to $\text{Re } \lambda(J) < 0$, i.e., to local stability of the tatonnement $\dot{\nu}_i = k_i \text{TB}_i$ for any $k_i > 0$, so simple dynamic exchange-rate adjustment processes converge to the equilibrium.

Consequently the response matrix $R \equiv (-J)^{-1}G$, with $\nu = Rt$, has the same eigenspaces and eigenvalues g_S/j_S and g_D/j_D . With equal weights $w_{Aj} = 1/(N-1)$, the effective rate is the scale projection, $d\nu_A^E = \frac{1}{N-1}\mathbf{1}'\nu = (g_S/j_S)\bar{t}$ with $\bar{t} \equiv \frac{1}{N-1}\mathbf{1}'t$. Finally, the multilateral Marshall–Lerner condition (20) holds if and only if

$$j_S > 0 \quad \text{and} \quad j_D \geq j_S. \quad (23)$$

The scale eigenvalue j_S is the trade-balance response of a partner when all partners appreciate together against A , and j_D is the response when one partner appreciates against the others with no change in the average. The condition (23) says that the uniform direction must be stabilizing and the zero-sum direction at least as stabilizing. The off-diagonal entry of $-J$ is $b_J = (j_S - j_D)/(N-1)$, so $j_D \geq j_S$ is the sign condition in (20) and, given $j_S > 0$, positivity of the inverse follows. Under exchangeability the entire adjustment mechanism therefore reduces to two scalars, and the response to any tariff vector imposed by A to the two ratios g_S/j_S and g_D/j_D . The symmetric benchmark computes all four numbers in closed form.

5 The Symmetric Benchmark

This section applies the general framework of Section 4 to the nested-CES model. We first derive the linearized system and the adjustment coefficient D_N , then compute the four eigenvalues of Lemma 4.4 in closed form, and use $N = 3$ to illustrate the distinction between impact and equilibrium responses. Section 4 is model-free, but this section and Sections 6–7 characterize tariff responses at the *symmetric benchmark* of Section 5.1, with equal bilateral weights and balanced trade. Appendix B relaxes symmetry and examines which results survive.

5.1 The linearized system

Linearizing at a balanced free-trade baseline with normalized incomes, define the home share $h_i = \alpha_D$, within-import shares $b_{ij} = \beta_{ij}$, income shares $s_{ij} = m b_{ij}$ with $m \equiv \alpha_T(1 - \alpha_D)$, and flows $f_{ij} = s_{ij}\tilde{I}_i$, where $\sum_k f_{ki} = \sum_j f_{ij}$. All incomes and flows are measured in the common currency. Thus, $d \log \tilde{I}_i$ includes the valuation term ν_i in addition to any tariff revenue, while wages remain constant in local currency. Perturbing this baseline with tariffs dt_{ij} gives

$$dp_{ij} = \nu_j - \nu_i + dt_{ij} \quad (dp_{ii} = 0), \quad (24)$$

$$d \log P_{M_i} = \sum_{j \neq i} b_{ij} dp_{ij}, \quad d \log P_{T_i} = (1 - \alpha_D) d \log P_{M_i}, \quad (25)$$

$$d \log s_{ii} = -(1 - \eta)(1 - \alpha_D) d \log P_{M_i}, \quad (26)$$

$$d \log s_{ij} = \underbrace{(1 - \rho)(dp_{ij} - d \log P_{M_i})}_{\text{across origins}} + \underbrace{(1 - \eta) \alpha_D d \log P_{M_i}}_{\text{home vs. imports}}, \quad (27)$$

$$d \log \tilde{I}_i = \nu_i + \sum_{j \neq i} s_{ij} dt_{ij}, \quad (28)$$

$$d \text{TB}_i = \sum_{k \neq i} f_{ki} (d \log s_{ki} + d \log \tilde{I}_k - dt_{ki}) - \sum_{j \neq i} f_{ij} (d \log s_{ij} + d \log \tilde{I}_i - dt_{ij}). \quad (29)$$

The coefficients in (29) give the model-specific entries of J and G in (17). At $N = 2$ they reduce to the two-country calculation of Section 3.

At the symmetric baseline, Lemma D.1 in Appendix D reduces the general conditions of Section 4 to a single parameter restriction, showing that every off-diagonal entry of the full $N \times N$ Jacobian is the same positive multiple of

$$\tilde{J}_{il} = \frac{m}{(N-1)^2} D_N \quad (l \neq i), \quad D_N \equiv N \alpha_D (\eta - 1) + (N - 2) \rho + 1. \quad (30)$$

Thus, weak gross substitutability holds if and only if $D_N \geq 0$. The strict inequality $D_N > 0$ implies the multilateral Marshall–Lerner condition (20): every off-diagonal entry is then strictly positive, so the irreducibility and $\tilde{J}_{iA} > 0$ conditions in Proposition 4.2 hold automatically. At $D_N = 0$, weak gross substitutability still holds, but $\tilde{J}$ and J vanish, so we exclude this boundary case. If $D_N < 0$, the off-diagonal entries of J are negative and the sign condition in (20) fails. Hence, under symmetry, $D_N > 0$ is equivalent to the multilateral Marshall–Lerner condition. Since $\rho > 0$, $\eta \geq 1$ is sufficient for $D_N \geq 1 > 0$ for every N .

Symmetry therefore reduces the adjustment mechanism to a fixed matrix scaled by D_N . We refer to D_N as the model's *multilateral trade-balance adjustment coefficient*: its sign determines whether exchange-rate adjustment is stabilizing, while its magnitude governs the strength of that adjustment. In particular,

$$\eta \geq 1 \implies D_N > 0 \iff \text{multilateral Marshall–Lerner condition (20) under symmetry}, \quad (31)$$

with $\eta \geq 1$ sufficient but not necessary. At $N = 2$, Section 3 showed that $D_2 = \varepsilon_X + \varepsilon_M - 1$, so $D_2 > 0$ is exactly the textbook Marshall–Lerner condition. The N -country responses below can therefore be read as tariff-induced reallocation forces divided by the strength of trade-balance adjustment. The numerators combine the components of F , while D_N scales the common denominator. Because $(-J)^{-1}$ combines the entire disturbance vector, an individual F_i does not by itself determine the sign of the corresponding exchange-rate response.

5.2 The four eigenvalues

At the symmetric benchmark the partners of A are exchangeable, so Lemma 4.4 applies and the response to any tariff vector $t = (t_j)_{j \neq A}$ imposed by A is determined by the four scalars (g_S, g_D, j_S, j_D) . We compute the impact eigenvalues directly from (29) and the adjustment eigenvalues from Lemma D.1.

Impact eigenvalues. Hold exchange rates fixed and let A impose t , with average $\bar{t} = \frac{1}{N-1} \sum_{j \neq A} t_j$. A partner i imposes no tariff, so its own import shares and its exports to other partners are unchanged, and (29) reduces to the flow from A . Using $dp_{Ai} = t_i$, $d \log P_{MA} = \bar{t}$, and $d \log \tilde{I}_A = m \bar{t}$ from (24)–(28),

$$\begin{aligned} d \text{TB}_i \big|_{\nu \text{ fixed}} &= f_{Ai} (d \log s_{Ai} + d \log \tilde{I}_A - t_i) = \frac{m}{N-1} \left[((1-\rho) - 1)(t_i - \bar{t}) + ((1-\eta)\alpha_D + m - 1)\bar{t} \right] \\ &= \frac{m}{N-1} \left[-\rho_1^* \bar{t} - \rho(t_i - \bar{t}) \right]. \end{aligned} \quad (32)$$

A uniform tariff, $t_i = \bar{t}$ for all i , kills the cross-origin term and leaves $-\rho_1^*$ per unit of flow; a zero-sum tariff, $\bar{t} = 0$, kills the price-index and income terms and leaves $-\rho$ per unit of flow. Hence

$$g_S = -\frac{m \rho_1^*}{N-1}, \quad g_D = -\frac{m \rho}{N-1}, \quad \frac{g_D}{g_S} = \frac{\rho}{\rho_1^*}. \quad (33)$$

Both impact eigenvalues are negative: a tariff worsens every partner's trade balance on average, and worsens it more for partners taxed above the average. Their ratio does not depend on N . For the unilateral tariff $t = d\tau \mathbf{e}_B$, which has $\bar{t} = d\tau/(N-1)$ and deviations $\tilde{t}_B = \frac{N-2}{N-1} d\tau$, $\tilde{t}_C = -\frac{d\tau}{N-1}$, the impact vector is

$$F_B = -\frac{m[\rho_1^* + (N-2)\rho]}{(N-1)^2} < 0, \quad F_C = \frac{m(\rho - \rho_1^*)}{(N-1)^2}, \quad (34)$$

so at impact the bystander benefits if and only if $\rho > \rho_1^*$, for every N .

Adjustment eigenvalues. Deleting row and column A from the full Jacobian in Lemma D.1, the reduced matrix has diagonal $-\frac{m}{N-1} D_N$ and off-diagonal $\frac{m}{(N-1)^2} D_N$, so

$$-J = c(N\mathbf{I} - \mathbf{1}\mathbf{1}'), \quad c \equiv \frac{m D_N}{(N-1)^2}, \quad j_S = c = \frac{m D_N}{(N-1)^2}, \quad j_D = Nc = \frac{N m D_N}{(N-1)^2}, \quad (35)$$

since $\mathbf{1}\mathbf{1}'$ acts as $N-1$ on the constant vector and as zero on the zero-sum subspace. The condition (23) is $c > 0$, which is $D_N > 0$, and the ratio $j_D/j_S = N$ holds for every parameter value: exchange-rate adjustment absorbs a zero-sum disturbance N times faster than a uniform one, because a partner that appreciates alone loses competitiveness against $N-1$ other suppliers, whereas partners that appreciate together lose it only against A .

Response eigenvalues. Dividing,

$$\lambda_S \equiv \frac{g_S}{j_S} = -\frac{(N-1)\rho_1^*}{D_N}, \quad \lambda_D \equiv \frac{g_D}{j_D} = -\frac{(N-1)\rho}{N D_N}, \quad \frac{\lambda_D}{\lambda_S} = \frac{\rho}{N \rho_1^*}. \quad (36)$$

Under (20) both eigenvalues are negative. The response to any t is $\nu = \lambda_S \bar{t} \mathbf{1} + \lambda_D \tilde{t}$, with $\tilde{t} \equiv t - \bar{t} \mathbf{1}$. Substituting the unilateral loadings gives the three unilateral slopes,

$$\frac{d \log e_{AB}}{d\tau} = -\frac{N\rho_1^* + (N-2)\rho}{N D_N} < 0, \quad \frac{d \log e_{AC}}{d\tau} = \frac{\rho - N\rho_1^*}{N D_N}, \quad \frac{d \log e_{BC}}{d\tau} = \frac{(N-1)\rho}{N D_N} > 0. \quad (37)$$

These expressions reduce to (15) at $N = 2$. Direct inversion of the reduced two-equation system for (ν_B, ν_C) , given in Appendix D, yields the same expressions. The next subsection uses $N = 3$ to distinguish the initial trade-balance effects from the equilibrium exchange-rate responses.

5.3 Three countries: impact versus equilibrium thresholds

With $N = 3$, $\beta_{ij} = \frac{1}{2}$ and $s_{ij} = m/2$. Collecting (29) for B and C gives the reduced system in disturbance-adjustment form:

$$J = -\frac{mD_3}{4} \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \quad F = -\frac{m}{4} \begin{pmatrix} \rho + \rho_1^* \\ \rho_1^* - \rho \end{pmatrix}, \quad D_3 = 3\alpha_D(\eta - 1) + \rho + 1. \quad (38)$$

The initial disturbances are $F_B = -\frac{m}{4}(\rho + \rho_1^*) < 0$ and $F_C = \frac{m}{4}(\rho - \rho_1^*)$, the $N = 3$ case of (34). The target B therefore always moves toward deficit. For the bystander C , trade diversion raises exports, while lower income in B and substitution toward A 's home tradable work in the opposite direction. The net effect on C is positive if and only if $\rho > \rho_1^*$, the impact ratio $g_D/g_S = \rho/\rho_1^*$ exceeding one. Inverting the system gives

$$\begin{pmatrix} \nu_B \\ \nu_C \end{pmatrix} = (-J)^{-1} F d\tau = -\frac{1}{3D_3} \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} \rho + \rho_1^* \\ \rho_1^* - \rho \end{pmatrix} d\tau = \frac{1}{3D_3} \begin{pmatrix} -(\rho + 3\rho_1^*) \\ \rho - 3\rho_1^* \end{pmatrix} d\tau. \quad (39)$$

Proposition 5.1 (Three-country threshold). *With $D_3 > 0$,*

$$\frac{d \log e_{AB}}{d\tau} = -\frac{\rho + 3\rho_1^*}{3D_3} < 0, \quad \boxed{\frac{d \log e_{AC}}{d\tau} = \frac{\rho - 3\rho_1^*}{3D_3}} \quad \frac{d \log e_{BC}}{d\tau} = \frac{2\rho}{3D_3} > 0. \quad (40)$$

A always appreciates against B, B always depreciates against C, and A depreciates against the untariffed C if and only if $\rho > \rho_3^ \equiv 3\rho_1^*$.*

The condition $F_C > 0$, or $\rho > \rho_1^*$, says that C benefits at unchanged exchange rates; it does not imply that the A – C bilateral rate reverses. By the sign rule, $d\nu_C/d\tau \propto F_B + 2F_C \propto \rho - 3\rho_1^*$. Thus, C 's equilibrium exchange rate depends not only on its own diversion gain but also on B 's deterioration. Reversal requires the former to be large enough to outweigh the latter. In eigen terms, the impact ratio ρ/ρ_1^* becomes the equilibrium ratio $\rho/(3\rho_1^*)$ because the zero-sum direction is absorbed by adjustment three times faster than the uniform direction, $j_D = 3j_S$ in (35).

Corollary 5.2 (Single elasticity). *With $\rho = \eta = \sigma$, $\rho_3^* - \sigma = \sigma(3\alpha_D - 1) + 3(1 - \alpha_D)(1 - \alpha_T) \geq 0$ whenever $\alpha_D \geq 1/3$, for any α_T , with equality only at $\alpha_D = 1/3$, $\alpha_T = 1$. The reversal is therefore impossible. At the equal-weights point $\alpha_D = 1/3$, $\alpha_T = 3/4$, $d \log e_{AC}/d\tau = -1/(12\sigma) \rightarrow 0^-$.*

When domestic and foreign tradables enter a single CES nest, the diversion gain therefore cannot offset B 's deterioration when $\alpha_D \geq 1/3$. More generally, $3\rho_1^* \geq \eta$ whenever $\alpha_D \geq 1/3$, so a bilateral depreciation of A against C requires $\rho > \eta$. A cross-origin elasticity above the home-import elasticity is therefore necessary, but not sufficient.

6 Two Results and Their Decomposition

6.1 Bilateral ambiguity and effective-rate preservation

Two main results follow from (36). First, bilateral exchange rates need not all move in the same direction.

Theorem 6.1 (Bystander threshold). *Under (20), the bystander bilateral rate reverses if and only if*

$$\boxed{\rho > \rho_N^* = N\rho_1^*}. \quad (41)$$

Theorem 6.2 (NEER preservation). *Under symmetry, a unilateral tariff appreciates the tariffing country's NEER for every $N \geq 2$ and every ρ satisfying (20).*

Both follow in one line from (36). A unilateral tariff $t_B = d\tau$ has $\bar{t} = d\tau/(N-1)$, $\tilde{t}_B = \frac{N-2}{N-1} d\tau$, and $\tilde{t}_C = -d\tau/(N-1)$ for every bystander, so $\nu = \lambda_S \bar{t} \mathbf{1} + \lambda_D \tilde{t}$ gives

$$\frac{d \log e_{AC}}{d\tau} = - \underbrace{\frac{\rho_1^*}{D_N}}_{\text{scale}} + \underbrace{\frac{\rho}{ND_N}}_{\text{discrimination}} = \frac{\rho - N\rho_1^*}{ND_N}, \quad \frac{d \log e_{AB}}{d\tau} = - \frac{\rho_1^*}{D_N} - \frac{(N-2)\rho}{ND_N}, \quad \frac{d\nu_A^E}{d\tau} = - \frac{\rho_1^*}{D_N}. \quad (42)$$

The effective rate is the scale projection of Lemma 4.4, and the gap between target and bystander is pure discrimination,

$$\frac{d\nu_A^E}{d\tau} = \frac{\nu_B + (N-2)\nu_C}{N-1} = \frac{\lambda_S}{N-1} = \boxed{- \frac{\rho_1^*}{D_N}} < 0, \quad \nu_B - \nu_C = \lambda_D d\tau = - \frac{(N-1)\rho}{ND_N} d\tau. \quad (43)$$

Theorem 6.2 is the boxed expression in (43): $\rho_1^* > 0$ by (13) and $D_N > 0$ under (20). Theorem 6.1 is the crossing point of the two components for the bystander in (42): the scale component appreciates A against C , the discriminatory component depreciates it, since C is taxed below the average, and A depreciates against C if and only if the second dominates. Because $|\bar{t}| = |\tilde{t}_C| = d\tau/(N-1)$, this is the comparison $|\lambda_D| > |\lambda_S|$, i.e., $\rho/N > \rho_1^*$. Against the target the two components reinforce, so the appreciation against B is unconditional.

The factor N in the threshold is an adjustment fact, not an impact fact. At impact, the unilateral tariff loads the scale and discriminatory disturbances with equal magnitude $1/(N-1)$, and their strengths stand in the ratio $g_D/g_S = \rho/\rho_1^*$, which carries no N : by (34), the bystander's trade balance improves at unchanged exchange rates whenever $\rho > \rho_1^*$, for every N . Trade diversion is not spread thinner across bystanders as N grows. The N enters entirely through $j_D/j_S = N$ in

(35): the zero-sum disturbance that favors the bystander is absorbed by exchange-rate adjustment N times faster than the uniform disturbance that works against it, so the equilibrium comparison is ρ/N against ρ_1^* . We refer to this adjustment fact as *dilution*. In the nested-CES model, the resulting threshold is exactly $N\rho_1^*$.² With $\rho = \eta = \sigma$, $\rho_N^* - \sigma = \sigma(N\alpha_D - 1) + N(1 - \alpha_D)(1 - \alpha_T) \geq 0$ whenever $\alpha_D \geq 1/N$. The reversal is therefore impossible in the home-biased region when the two substitution margins share a common elasticity.

Cross-origin substitution can reverse the response of an individual bystander rate because it reallocates expenditure across foreign suppliers. Under symmetry this reallocation is a zero-sum disturbance, so it has no scale projection and cannot reverse the aggregate response. This does not make the magnitude of the NEER response independent of ρ , since ρ still enters D_N .

6.2 Scale and discrimination in general tariff vectors

The preceding subsection analyzes a single bilateral tariff. This subsection characterizes the response to an arbitrary tariff vector imposed by A and shows that, under symmetry, Theorems 6.1 and 6.2 are two components of one decomposition.

Let $t = (t_j)_{j \neq A}$ collect A 's tariff changes, $t_j \equiv dt_{Aj}$, and split it into a scale component and a discriminatory component,

$$t_j = \bar{t} + \tilde{t}_j, \quad \bar{t} \equiv \frac{1}{N-1} \sum_{j \neq A} t_j, \quad \sum_{j \neq A} \tilde{t}_j = 0. \quad (44)$$

The scale component is the average tariff A levies on its partners, and the discriminatory component records how far each partner's treatment departs from that average. By linearity and the symmetry of the partners, the response to t is the sum of the unilateral responses in (37): each bilateral rate responds to its own tariff with the own-target coefficient and to every other partner's tariff with the bystander coefficient,

$$\nu_j = \alpha t_j + \beta \sum_{k \neq j, A} t_k, \quad \alpha \equiv -\frac{N\rho_1^* + (N-2)\rho}{ND_N}, \quad \beta \equiv \frac{\rho - N\rho_1^*}{ND_N}. \quad (45)$$

In matrix form $\nu = R t$ with $R = (\alpha - \beta)I + \beta \mathbf{1}\mathbf{1}'$, whose eigenvalues $\alpha + (N-2)\beta$ and $\alpha - \beta$ are λ_S and λ_D in (36).

Proposition 6.3 (Scale–discrimination decomposition). *At the symmetric benchmark, under (20), the response of A 's bilateral rate against any partner j to any tariff vector t imposed by A is the sum of a scale term, common to all partners and proportional to the average tariff, and a relative-*

²The exact linearity in N is a symmetric nested-CES result. At any balanced baseline where A and a bystander both import from both foreign origins, sufficiently strong cross-origin substitution still reverses the bystander rate, provided the multilateral Marshall–Lerner condition continues to hold (Appendix B). Appendix B also shows that the NEER cancellation survives to leading order within a structured asymmetric family but can reverse for a sufficiently under-weighted target, and Appendix C collects the correspondence across N .

treatment term, proportional to the gap between j 's tariff and that average:

$$\nu_j = \lambda_S \bar{t} + \lambda_D \tilde{t}_j, \quad d\nu_A^E = \lambda_S \bar{t}, \quad \nu_j - d\nu_A^E = \lambda_D \tilde{t}_j, \quad d \log e_{jk} = \lambda_D (t_k - t_j) \quad (j, k \neq A). \quad (46)$$

The effective rate depends only on the scale component, bilateral deviations from the effective rate depend only on the discriminatory component, and cross rates between partners depend only on tariff differences.

The parameters separate with the components. ρ_1^* enters only λ_S : home switching and expenditure absorption respond to the overall level of protection and move every bilateral rate equally. ρ enters only λ_D : cross-origin substitution responds only to differences in treatment across partners and, being a pure reallocation, averages to zero. D_N scales both, so the adjustment coefficient governs the magnitude of every response without affecting the comparison between the two components. Under (20) both eigenvalues are negative. The scale component appreciates A against every partner, while the discriminatory component appreciates A against partners taxed above the average ($\tilde{t}_j > 0$) and depreciates it against partners taxed below the average ($\tilde{t}_j < 0$).

The sign of any individual bilateral response therefore turns on two numbers, the average tariff and the partner's deviation from it.

Corollary 6.4 (Relative treatment). *Under the conditions of Proposition 6.3, with $\bar{t} > 0$: (i) bilateral responses are ordered by the tariffs, $t_j > t_k$ implies $\nu_j < \nu_k$, so A appreciates most against the partners it taxes most; (ii) A depreciates against partner j if and only if*

$$\frac{\rho}{N} (\bar{t} - t_j) > \rho_1^* \bar{t} \quad \Longleftrightarrow \quad \frac{t_j}{\bar{t}} < 1 - \frac{N\rho_1^*}{\rho}, \quad (47)$$

which requires $\rho > N\rho_1^*$ and a tariff on j below the fraction $1 - N\rho_1^*/\rho$ of the average.

Consider A tariffing every partner, but by varying amounts. Every bilateral rate then carries the same scale appreciation $\lambda_S \bar{t}$, and the ranking of responses across partners is fixed by the tariffs alone. A partner taxed above the average sees A appreciate by more than the effective rate. A partner taxed below the average sees a smaller appreciation, and A depreciates against it only if its tariff is low enough relative to the average to satisfy (47). The untaxed bystander of Theorem 6.1 is the case $t_j = 0$, for which (47) reduces to $\rho > N\rho_1^*$. For a particular partner C , the response is $\nu_C = \lambda_S \bar{t} + \lambda_D (t_C - \bar{t})$: the A - C bilateral rate is pinned down by the scale of the policy and by where C sits in the distribution of tariffs, and by nothing else. Quantifying a bilateral response under a general tariff vector thus requires the average tariff, the partner's deviation from it, and the two eigenvalues.

The decomposition also covers tariffs on several partners at once.

Corollary 6.5 (Number of targets). *If A raises its tariff by τ on a set of k partners, $1 \leq k \leq N-1$, then for every untargeted partner C and every targeted partner B ,*

$$\frac{d \log e_{AC}}{\tau} = \frac{k(\rho - N\rho_1^*)}{ND_N}, \quad \frac{d \log e_{AB}}{\tau} = -\frac{k\rho_1^*}{D_N} - \frac{(N-1-k)\rho}{ND_N}, \quad \frac{d\nu_A^E}{\tau} = -\frac{k\rho_1^*}{D_N}. \quad (48)$$

The bystander reversal threshold is $N\rho_1^*$ for every $k \leq N - 2$.

Targeting more partners scales both components of the bystander response by the same factor k , so the threshold is unchanged and only the magnitude grows. At $k = N - 1$ the discriminatory component vanishes and the tariff is pure scale,

$$\frac{d \log e_{Aj}}{d\tau} = -\frac{(N-1)\rho_1^*}{D_N} = \frac{d\nu_A^E}{d\tau} \quad \forall j. \quad (49)$$

Because all foreign origins face the same tariff, there is no cross-origin reallocation. The elasticity ρ drops out of the numerator, every bilateral rate appreciates by the same amount, and the bilateral and effective responses coincide. The bilateral ambiguity under a discriminatory tariff therefore comes from reallocation across foreign suppliers rather than from protection itself.

6.3 Real exchange rates

From (10) and (6),

$$d \log q_{Aj} = \nu_j + \alpha_T (d \log P_{T_j}^{\text{own}} - d \log P_{T_A}^{\text{own}}). \quad (50)$$

For a tariff vector t the price-index term depends only on the scale component, since $d \log P_{M_A} = d\nu_A^E + \bar{t}$ and $d \log P_{M_j} = d\nu_A^E - \frac{N}{N-1}\nu_j$ for a partner that imposes no tariff, so

$$d \log q_{Aj} = \left(1 - \frac{mN}{N-1}\right) \nu_j - m \bar{t}, \quad dq_A^E = \left[\left(1 - \frac{mN}{N-1}\right) \lambda_S - m\right] \bar{t}, \quad d \log q_{Aj} - dq_A^E = \left(1 - \frac{mN}{N-1}\right) \lambda_D \tilde{t}_j. \quad (51)$$

The real effective rate is again scale-only, and real bilateral deviations are again discriminatory-only, attenuated by the pass-through factor. For a unilateral tariff, $\bar{t} = d\tau/(N-1)$ and both bilateral real exchange rates can be written as

$$d \log q_{Aj} = \left(1 - \frac{mN}{N-1}\right) \nu_j - \frac{m}{N-1} d\tau, \quad j = B, C. \quad (52)$$

The real exchange-rate response therefore combines the nominal response with a direct price-index effect that appreciates A in real terms. Setting $d \log q_{AC} = 0$ and using (37), for $m < 1/N$, gives

$$\rho_q^*(N) = \frac{[(N-1) - mN] N\rho_1^* + mN[N\alpha_D(\eta-1) + 1]}{(N-1)(1-mN)} > N\rho_1^*. \quad (53)$$

Averaging (52) gives

$$\frac{dq_A^E}{d\tau} = -\left(1 - \frac{mN}{N-1}\right) \frac{\rho_1^*}{D_N} - \frac{m}{N-1} < 0 \quad \text{for all } \rho, N \text{ } (m < \frac{N-1}{N}). \quad (54)$$

Proposition 6.6 (Real rates). *Under (20), (i) the real bilateral reversal threshold exceeds the nominal threshold, $\rho_q^*(N) > N\rho_1^*$, and (ii) the REER appreciates for every ρ and N , $dq_A^E/d\tau < 0$.*

Both results follow from the direct price-index effect: the tariff raises A 's consumer prices at a given nominal exchange rate, making a bilateral real depreciation harder to obtain and reinforcing the effective appreciation.

7 Trade Wars and Preferential Tariffs

The decomposition extends to configurations in which several countries impose tariffs, since each tariffing country's vector decomposes as in Section 6.2 and the responses superpose. Under symmetry any country can serve as the reference country of Proposition 6.3, so for a tariffing country i with vector $t^{(i)}$ over its partners,

$$d \log e_{ij} = \lambda_S \bar{t}^{(i)} + \lambda_D \bar{t}_j^{(i)}, \quad d \log e_{jk} = \lambda_D (t_k^{(i)} - t_j^{(i)}) \quad (j, k \neq i). \quad (55)$$

A tariffing country's scale component therefore moves its own bilateral rates one for one and cancels from every cross rate between its partners, because it moves those partners equally. Its discriminatory component enters every rate between differently treated countries.

7.1 Trade wars

Bilateral war. Adding the mirror shock $dt_{BA} = d\tau$ to the unilateral tariff gives

$$\left. \frac{d \log e_{AB}}{d\tau} \right|^w = 0, \quad \left. \frac{d \log e_{AC}}{d\tau} \right|^w = \frac{\rho - \rho_1^*}{D_N}, \quad \left. \frac{d\nu_A^E}{d\tau} \right|^w = \frac{N-2}{N-1} \frac{\rho - \rho_1^*}{D_N}. \quad (56)$$

Proposition 7.1 (Trade war threshold). *Under (20), in a symmetric trade war the belligerents' effective rates depreciate, and every bystander appreciates against both, if and only if $\rho > \rho_1^*$, independently of N .*

In the language of (55), B 's retaliation contributes to the A – C rate only through its discriminatory component, since its scale component appreciates B equally against A and C and cancels from e_{AC} :

$$\left. \frac{d \log e_{AC}}{d\tau} \right|^w = \underbrace{-\frac{\rho_1^*}{D_N}}_{A's \text{ scale}} + \underbrace{\frac{\rho}{ND_N}}_{A's \text{ discrimination}} + \underbrace{\frac{(N-1)\rho}{ND_N}}_{B's \text{ discrimination}} = \frac{\rho - \rho_1^*}{D_N}. \quad (57)$$

The two discriminatory contributions sum to ρ/D_N regardless of N , which is why the threshold falls from $N\rho_1^*$ to ρ_1^* . In eigen terms, A 's tariff loads the discriminatory disturbance g_D on the A – C rate with weight $1/(N-1)$ and B 's retaliation loads it with weight 1 on the same pair, so the two contributions sum to $-g_D \frac{N}{N-1}/j_D = -g_D/(j_S(N-1))$ by $j_D = Nj_S$, and the bystander war response is

$$\left. \frac{d \log e_{AC}}{d\tau} \right|^w = \frac{g_S - g_D}{j_S(N-1)}, \quad (58)$$

the gap between the two impact disturbances divided by scale adjustment alone. Retaliation removes the factor N because the second discriminatory disturbance singles out the same pair and exactly offsets the faster absorption of zero-sum disturbances, while adding no scale component to the A – C rate. On the A – B rate the two countries' components are mirror images and cancel exactly. At $\eta = 1$, $\rho_1^* = 1 - m < 1$.

Global retaliation. Suppose A raises its tariff by $d\tau$ on every partner and every partner retaliates with $d\tau$ on A .

Proposition 7.2 (Global retaliation). *Under (20), if A taxes all $N - 1$ partners by $d\tau$ and each partner taxes A by $d\tau$, then*

$$\frac{d \log e_{Aj}}{d\tau} = \frac{d\nu_A^E}{d\tau} = \frac{(N-2)(\rho - \rho_1^*)}{D_N} \quad \forall j, \quad (59)$$

and all cross rates between partners are unchanged. A depreciates against every partner if and only if $\rho > \rho_1^$.*

A 's own tariff is pure scale and appreciates it by $(N-1)\rho_1^*/D_N$ against everyone. Each partner's retaliation is a unilateral tariff on A . Its scale component appreciates that partner against A by ρ_1^*/D_N and cancels from every other rate involving A , leaving a net scale appreciation of $(N-2)\rho_1^*/D_N$. Its discriminatory component singles out A and, summed over the $N-1$ retaliating partners, depreciates A by $(N-2)\rho/D_N$ against each. The threshold is again ρ_1^* , and at $N=2$ the response vanishes by symmetry, as in the bilateral war.

7.2 Competing exporters

A standard model in the preferential-trade-agreement (PTA) literature has one importer and two competing exporters, following the tradition of Viner (1950) and Mundell (1964). Importer A holds only the numeraire good y , while exporters B and C hold good x . Preferences are quasilinear, $U_i = u_i(x_i) + y_i$. Country A levies specific tariffs t_B and t_C . Let q_j denote the exporter price and p the domestic price. Market clearing requires

$$p = q_B + t_B = q_C + t_C, \quad M_A(p) = E_B(p - t_B) + E_C(p - t_C), \quad M'_A < 0, \quad E'_j > 0, \quad (60)$$

where $M_A(p) = x_A^d(p)$ and $E_j(q_j) = \omega_j - x_j^d(q_j)$, with u'_i equal to the local price. Differentiating with respect to t_B gives

$$\frac{dp}{dt_B} = \frac{E'_B}{E'_B + E'_C - M'_A} \in (0, 1), \quad \frac{dq_B}{dt_B} = -\frac{E'_C - M'_A}{E'_B + E'_C - M'_A} < 0, \quad \frac{dq_C}{dt_B} = \frac{dp}{dt_B} > 0. \quad (61)$$

Proposition 7.3 (Competing-exporter terms-of-trade effect). *A discriminatory tariff on B worsens B 's terms of trade and improves C 's terms of trade.*

7.3 Preferential tariffs as discrimination without scale

In our model, an improvement in C 's terms of trade is equivalent to a rise in e_{AC} by (12), so the two models can be compared directly: C 's terms of trade improve unconditionally in the competing-exporter model, while the same outcome requires $\rho > 3\rho_1^*$ in ours.

A preferential tariff is a discriminatory vector by construction, but in our model it also carries a scale component. Lowering A 's tariff on B alone is $t = -\tau \mathbf{e}_B$, the negative of the unilateral tariff, with $\bar{t} = -\tau/(N-1)$ and $\tilde{t}_C = \tau/(N-1)$. By Proposition 6.3 the effect on the non-member's currency is the compromise of Section 6.1 with the signs reversed: the scale component depreciates A against C because protection falls, the discriminatory component appreciates it because C is now taxed above the average, and C 's terms of trade worsen, the canonical direction, only if $\rho > N\rho_1^*$.

The difference between the two models is therefore the presence of the scale component. The competing-exporter model has two foreign suppliers of a common importable and quasilinear preferences, while our model has country-specific differentiated tradables and nested-CES preferences. Neither model is a special case of the other. The threshold at which discrimination overtakes scale at $N = 3$ can be written as

$$\rho_3^* = 3\rho_1^* = \underbrace{3}_{B-C \text{ linkage}} + \underbrace{3\alpha_D(\eta-1)}_{\text{home switching}} - \underbrace{3\alpha_T(1-\alpha_D)}_{\text{openness offset}}. \quad (62)$$

The first term captures the effects operating through B - C trade: lower income in B reduces its purchases from C , while relative-price changes lead C to substitute toward cheaper goods from B . The second is A 's substitution toward its own tradable, and the final term works in the opposite direction, since a larger import share gives the tariff more foreign expenditure to redirect, strengthening trade diversion and lowering the threshold.

In the language of Section 6.2, the canonical environment has no scale channel. Country A has no competing home tradable, so there is no home-switching margin, and quasilinearity with a traded numeraire removes the income and absorption responses. The overall level of protection is absorbed by the domestic price p rather than by an exchange-rate adjustment. In eigen terms, the competing-exporter benchmark is the case $g_S = 0$. What remains is the analogue of the discriminatory component alone, direct reallocation between the two foreign suppliers, which has an unambiguous sign because $M'_A < 0$ and $E'_j > 0$. A single component cannot produce a crossing, so the terms-of-trade effects of a preference are unconditional. In our model the same discriminatory force is present, but it must overcome the scale response that the level of protection induces, and the threshold measures how strong it must be.

This is an economic comparison rather than a formal nesting result. Quasilinear preferences cannot be obtained from the nested-CES demand system by a parameter restriction, and (62) is useful for interpreting the threshold rather than mapping one model into the other. The classic competing-exporter result isolates the trade-diversion force. Our model adds home substitution, income effects, and third-country trade, which can offset that force. The condition $\rho > 3\rho_1^*$ states how strong cross-origin substitution must be for trade diversion to dominate.

Read in these terms, the PTA literature studies the discriminatory component of trade policy, and the environments differ mainly in whether a scale channel exists to offset it. The broader PTA literature differs in which of these margins it retains. Competing-exporter models such as Bagwell and Staiger (1999) and Ornelas (2005) abstract from B - C trade and use quasilinear preferences, so the corresponding diversion effect is unopposed. Bloc and endowment models such as Krugman (1991) and Bond and Syropoulos (1996) instead abstract from home production of importables.

Viner’s (1950) identical-goods case corresponds, in the language of our model, to the limit $\rho \rightarrow \infty$. Kemp and Wan (1976) consider a more general customs-union environment and do not provide the corresponding unconditional terms-of-trade sign result. Applied GTAP-class and quantitative trade models retain analogous general-equilibrium forces, but to our knowledge do not characterize the reversal threshold analytically.

8 Conclusion

The general equilibrium response to a tariff can be written as $(-J)^{-1}F$. The vector F gives the trade-balance disturbances created by the tariff at unchanged exchange rates, while J describes how exchange-rate changes restore trade balance.

At $N = 2$, this reduces to the textbook Marshall–Lerner result: an import tariff appreciates the tariffing country’s currency. With three or more countries, a discriminatory tariff also reallocates expenditure across foreign suppliers. The tariffing country still appreciates against the target, but its exchange rate against an untariffed bystander can move in either direction when cross-origin substitution is sufficiently strong.

Under symmetry, this bilateral ambiguity disappears after aggregation. The tariffing country’s NEER appreciates for every admissible ρ and N , even though individual bilateral rates may move in opposite directions. The main distinction is therefore between substitution between home and foreign goods, which determines the sign of the effective exchange-rate response, and substitution across foreign suppliers, which determines how that adjustment is distributed across bilateral exchange rates.

Under symmetry these two margins are the two components of any tariff vector. The average tariff determines the effective rate through home switching and expenditure absorption, while deviations from the average determine bilateral rates around it through cross-origin substitution. Trade wars layer such components across countries, and the canonical preferential-tariff results are the discriminatory component operating without a scale channel to offset it.

A Exact Cobb–Douglas solution ($N = 2$)

At $\eta = 1$, expenditure shares are fixed at their weights. From (8), $I_A = w_A L_A / [1 - \frac{\tau}{1+\tau} m]$, and $TB_A = 0$ becomes $e m w_B L_B = m I_A / (1 + \tau)$:

$$e(\tau) = \frac{w_A L_A}{w_B L_B} \cdot \frac{1}{1 + (1 - m)\tau}, \quad \left. \frac{d \log e}{d\tau} \right|_{\tau=0} = -(1 - m) = -\left. \frac{\rho_1^*}{D_2} \right|_{\eta=1}. \quad (63)$$

Thus, $e(\tau)$ is decreasing in τ , so the sign of the linearized response in (15) is exact for all tariff levels in this case. Here $\eta = 1$ fixes the elasticity, not the weight α_D .

B Asymmetry

The disturbance-adjustment representation (18) and the multilateral Marshall–Lerner condition (20) do not require symmetry. The exact thresholds, the NEER cancellation, and the scale–discrimination decomposition in Sections 5–7 do. This appendix examines what survives without symmetry. Conditional on the multilateral Marshall–Lerner condition, the bilateral reversal result continues to hold at any balanced baseline where the tariffing country and the bystander each import from both foreign origins. The NEER result also survives to leading order within a structured asymmetric family.

A simple degree argument shows why the single-threshold results under symmetry do not extend directly to arbitrary trade networks. The elasticity ρ enters the share responses (27) only through $(1 - \rho)$, so every entry of J and F is linear in ρ . Each entry of $\text{adj}(-J)$ is a determinant of an $(N - 2) \times (N - 2)$ submatrix of $-J$ and is therefore a polynomial of degree at most $N - 2$ in ρ . It follows that each numerator $[\text{adj}(-J) F]_i$ in (18) is a polynomial of degree at most $N - 1$. Since $\det(-J) > 0$ under (20), a bilateral response can change sign only at a root of this numerator polynomial. Symmetry reduces the system to two unknowns and leaves numerators linear in ρ , producing the single thresholds in Proposition 5.1 and Theorem 6.1. At a general asymmetric baseline, the $N = 3$ numerator is already quadratic in ρ , as shown in (64), and for $N \geq 4$ a response may change sign more than once as ρ rises.

General asymmetric baseline. At any balanced baseline, (24)–(29) continue to hold with observed shares (b_{ij}, h_i) and incomes y_i as coefficients. For $N = 3$, the bystander slope has denominator $\det(-J) > 0$ and a numerator that is quadratic in ρ (derived in the appendix of the companion IMF working paper by Lu and Milkov, forthcoming):

$$\text{sign } \frac{d \log e_{AC}}{d\tau} = \text{sign } (c_2 \rho^2 + c_1 \rho + c_0), \quad c_2 = b_{AB} b_{AC} b_{CA} b_{CB} (1 - h_A)(1 - h_C) y_A y_C. \quad (64)$$

The coefficients c_1 and c_0 depend on the full pattern of trade shares and country sizes. A positive numerator at large ρ determines the equilibrium sign only if the adjustment mechanism remains regular. The result is therefore conditional on the multilateral Marshall–Lerner condition (20) continuing to hold at the relevant values of ρ , which ensures $\det(-J) > 0$. Under this condition, $c_2 > 0$ whenever A and C each import from both foreign origins. Sufficiently strong cross-origin substitution then reverses e_{AC} at any such baseline. The threshold is the largest root and equals $3\rho_1^*$ at the symmetric point. Away from symmetry, there is no universal bilateral threshold.

Structured asymmetry. Let the target receive a multiple κ of its symmetric bilateral share. This scaling remains comparable across N because the symmetric share falls as $1/(N-1)$. Assume the weight matrix is symmetric and balanced:

$$b_{AB} = b_{BA} = \frac{\kappa}{N-1}, \quad b_{AC} = b_{CA} = b_{BC} = b_{CB} = \frac{1 - \frac{\kappa}{N-1}}{N-2}, \quad b_{CC'} = \frac{1 - 2b_{CA}}{N-3}. \quad (65)$$

The reduced system again has two unknowns and can be solved in closed form. With NEER weights $w_{Aj} = b_{Aj}$, the response is a rational function of (ρ, N, κ) that reduces to $-\rho_1^*/D_N$ at $\kappa = 1$. Its numerator is $-\kappa\rho_1^*$ times a quadratic $Q(\rho)$ whose leading coefficient is proportional to $(\kappa-1)(N-1-\kappa)$.

Proposition B.1 (Asymmetric NEER). *Holding κ fixed as $N \rightarrow \infty$,*

$$N \frac{d\nu_A^E}{d\tau} \longrightarrow -\kappa \frac{\rho_1^*}{\rho + \alpha_D(\eta-1)} = -\kappa \lim_{N \rightarrow \infty} \frac{N\rho_1^*}{D_N}. \quad (66)$$

To leading order, asymmetric exposure scales the symmetric NEER response by the relative importance of the target without changing its sign. At finite N , if $\kappa \geq 1$, all coefficients of Q are positive for large N , so the effective rate appreciates for every ρ . If $\kappa < 1$, Q has a single positive root,

$$\rho_E^*(\kappa, N) = \frac{N\rho_1^*}{1-\kappa} (1 + O(N^{-1})),$$

above which the NEER depreciates. When the target is under-weighted, depreciations against the many bystanders can outweigh the appreciation against B . As $\kappa \rightarrow 0$, $\rho_E^* \rightarrow N\rho_1^*$, so the reversal threshold remains of order N . In the language of Lemma 4.4, asymmetric weights break the exchangeability of the partners: G and $-J$ no longer commute, so they no longer share the constant and zero-sum eigenvectors, and the discriminatory component of the tariff leaks into the effective rate; the $\kappa < 1$ reversal is this leakage. The NEER result is therefore exact under symmetry and approximately robust within this structured asymmetric family. We do not claim robustness to arbitrary asymmetric trade networks.

D Proofs

Throughout, $m \equiv \alpha_T(1 - \alpha_D)$, $P \equiv \rho + \alpha_D(\eta - 1)$, and all derivatives are evaluated at the balanced free-trade baseline of Section 5.1.

Proof of Proposition 3.1. The linearization in Section 3 gives (14), with $D_2 = 1 + 2\alpha_D(\eta - 1)$ and $\rho_1^* = 1 - m + \alpha_D(\eta - 1)$, and the boxed slope (15) follows. For the elasticity form, hold income fixed and let $M(p)$ denote import volume at consumer price $p = p_{AB}$. Since import value is $s_{AB}I_A$,

$$\varepsilon_M \equiv -\frac{\partial \log M}{\partial \log p} = 1 - \frac{\partial \log s_{AB}}{\partial \log p} = 1 - (1 - \eta)\alpha_D = 1 + \alpha_D(\eta - 1).$$

By symmetry, $\varepsilon_X = 1 + \alpha_D(\eta - 1)$. Differentiating $\text{TB}_A(e, \tau) = X(1/e) - eM((1 + \tau)e)$ at $\tau = 0$ and using balanced trade, $X = eM$, gives $\partial \text{TB}_A / \partial e = M(\varepsilon_X + \varepsilon_M - 1)$. Hence $\varepsilon_X + \varepsilon_M - 1 = 2\alpha_D(\eta - 1) + 1 = D_2$, so the stability condition $D_2 > 0$ is exactly $\varepsilon_X + \varepsilon_M > 1$. Since $F = m\rho_1^* > 0$ by (13), the slope $-\rho_1^*/D_2$ is negative. $\square$

Proof of Proposition 4.2. Scaling every currency value e_{Al} by a common factor leaves all relative

prices in (24) unchanged and scales every common-currency income, and hence every flow f_{ij} and trade balance TB_i , by the same factor. Thus, TB_i is homogeneous of degree one in the currency values. By Euler's theorem, $\sum_l \tilde{J}_{il} = TB_i$, which is zero at the balanced baseline, so $\sum_l \tilde{J}_{il} = 0$ for all i . Equivalently, in (29), a common shift in all ν_l affects only the income terms, whose export and import contributions cancel by baseline balance. Summing (9) over i gives $\sum_i TB_i \equiv 0$, so $\sum_i \tilde{J}_{il} = 0$ for all l . Under Assumption 1, $\tilde{J}_{il} \geq 0$ for $l \neq i$, so $\tilde{J}_{ii} = -\sum_{l \neq i} \tilde{J}_{il} \leq 0$. Deleting row and column A then gives

$$|J_{ii}| = \sum_{l \neq i, A} J_{il} + \tilde{J}_{iA} \geq \sum_{l \neq i, A} J_{il}, \quad (67)$$

with strict inequality in every row for which $\tilde{J}_{iA} > 0$.

Thus, $-J$ is a Z-matrix with nonpositive off-diagonal entries, nonnegative diagonal entries, weak diagonal dominance, irreducibility, and strict diagonal dominance in at least one row. Its diagonal is strictly positive, since $|J_{ii}| = 0$ would force row i of J to vanish, contradicting irreducibility. Write $-J = D - B$, where $D = \text{diag}(-J) > 0$ and $B \geq 0$. Diagonal dominance implies that every row sum of $D^{-1}B$ is at most one and that at least one is strictly below one. With irreducibility, its spectral radius therefore satisfies $r \equiv \rho(D^{-1}B) < 1$. Hence

$$(-J)^{-1} = (I - D^{-1}B)^{-1}D^{-1} = \sum_{k \geq 0} (D^{-1}B)^k D^{-1} \geq 0.$$

Nonsingularity follows from $r < 1$. Moreover, $\det(-J) = \det D \cdot \det(I - D^{-1}B) > 0$: $\det D > 0$, and the eigenvalues $1 - \lambda$ of $I - D^{-1}B$ satisfy $|\lambda| \leq r < 1$, so real eigenvalues are positive and complex eigenvalues occur in conjugate pairs with positive products. Finally, the Gershgorin discs of $-J$ are centered at $|J_{ii}| > 0$ with radii no larger than $|J_{ii}|$. They therefore lie in the closed right half-plane and can intersect the imaginary axis only at the origin, which nonsingularity excludes. Hence $\text{Re } \lambda(-J) > 0$, or equivalently $\text{Re } \lambda(J) < 0$. $\square$

Proof of Corollary 4.3. The result follows directly from (18): $d\nu/d\tau = (-J)^{-1}F$, with $(-J)^{-1} = (\vartheta_{ij}) \geq 0$ elementwise by Proposition 4.2. $\square$

Proof of Lemma 4.4. Let M be an $(N-1) \times (N-1)$ matrix with $PMP' = M$ for every permutation matrix P . Conjugating by the transposition of i and j gives $M_{ii} = M_{jj}$, and conjugating by a permutation that sends the ordered pair (i, j) to (k, l) , $i \neq j$, $k \neq l$, gives $M_{ij} = M_{kl}$. Hence $M = aI + b\mathbf{1}\mathbf{1}'$. Since $\mathbf{1}'\mathbf{1} = N-1$, $M\mathbf{1} = [a + (N-1)b]\mathbf{1}$, and $Mv = av$ for every v with $\mathbf{1}'v = 0$, which gives (22) for $-J$ and G . For $j_S, j_D \neq 0$, $(-J)^{-1} = \frac{1}{j_D}I + \frac{1}{N-1}\left(\frac{1}{j_S} - \frac{1}{j_D}\right)\mathbf{1}\mathbf{1}'$, as direct multiplication verifies, so $(-J)^{-1}$ and G are both of the same form, commute, and share the two eigenspaces; the eigenvalues of $R = (-J)^{-1}G$ are the products g_S/j_S and g_D/j_D . Writing $t = \bar{t}\mathbf{1} + \tilde{t}$ with $\mathbf{1}'\tilde{t} = 0$ gives $\nu = Rt = (g_S/j_S)\bar{t}\mathbf{1} + (g_D/j_D)\tilde{t}$, and averaging with equal weights gives $d\nu_A^E = (g_S/j_S)\bar{t}$ because $\mathbf{1}'\tilde{t} = 0$. For (23), the off-diagonal entry of $-J$ is $b_J = (j_S - j_D)/(N-1)$, so $-J$ is a Z-matrix if and only if $j_D \geq j_S$. Given this, the off-diagonal entry of $(-J)^{-1}$ is $\frac{1}{N-1}(1/j_S - 1/j_D)$ and the diagonal entry is $1/j_D$ plus this quantity. If $j_D \geq j_S > 0$, both are nonnegative and $-J$ is nonsingular, so (20) holds. Conversely, if $j_S \leq 0$ then either $-J$ is singular or, with $j_S < 0$, one of $1/j_S - 1/j_D$ (when $j_D > 0$) and $1/j_D + \frac{1}{N-1}(1/j_S - 1/j_D) = \frac{1}{N-1}[1/j_S + (N-2)/j_D]$ (when

$j_D < 0$) is negative, so (20) fails. At $N = 2$ the zero-sum subspace is trivial and the condition reduces to $j_S > 0$. $\square$

Lemma D.1 (Full Jacobian at the symmetric baseline). *At the symmetric balanced baseline of Section 5.1, where $b_{ij} = 1/(N-1)$ and $f_{ij} = m/(N-1)$, the full $N \times N$ Jacobian of the nested-CES model is*

$$\tilde{J}_{il} = \frac{m}{(N-1)^2} D_N \quad (l \neq i), \quad \tilde{J}_{ii} = -\frac{m}{N-1} D_N, \quad D_N = N\alpha_D(\eta-1) + (N-2)\rho + 1. \quad (68)$$

Proof. Set $dt_{jk} = 0$, so $dp_{ij} = \nu_j - \nu_i$ and $d \log \tilde{I}_i = \nu_i$. Writing $S \equiv \sum_j \nu_j$, (25) gives

$$d \log P_{M_k} = \frac{S - N\nu_k}{N-1}, \quad \frac{\partial d \log P_{M_k}}{\partial \nu_l} = \frac{1 - N\delta_{kl}}{N-1}.$$

On the import side, $\sum_{j \neq i} (dp_{ij} - d \log P_{M_i}) = 0$, so the $(1-\rho)$ terms cancel when (27) is summed over $j \neq i$. Thus, $\sum_{j \neq i} d \log s_{ij} = (N-1)(1-\eta)\alpha_D d \log P_{M_i}$. Substituting into (29) gives

$$d \text{TB}_i = \frac{m}{N-1} \left[\sum_{k \neq i} (d \log s_{ki} + \nu_k) - (N-1)(1-\eta)\alpha_D d \log P_{M_i} - (N-1)\nu_i \right].$$

Fix $l \neq i$ and differentiate term by term, using $\sum_{k \neq i} \delta_{kl} = 1$ and $\sum_{k \neq i} (1 - N\delta_{kl}) = -1$:

$$\frac{\partial}{\partial \nu_l} \sum_{k \neq i} d \log s_{ki} = (1-\rho) \left(-1 + \frac{1}{N-1} \right) - \frac{(1-\eta)\alpha_D}{N-1} = -(1-\rho) \frac{N-2}{N-1} - \frac{(1-\eta)\alpha_D}{N-1}.$$

The export income terms contribute $\partial_{\nu_l} \sum_{k \neq i} \nu_k = 1$, the import-side price-index term contributes $-(1-\eta)\alpha_D$, and the import income term contributes zero. Collecting terms gives

$$\tilde{J}_{il} = \frac{m}{(N-1)^2} \left[(N-1) - (1-\rho)(N-2) + N\alpha_D(\eta-1) \right] = \frac{m}{(N-1)^2} D_N.$$

The diagonal follows from (19): $\tilde{J}_{ii} = -(N-1)\tilde{J}_{il} = -\frac{m}{N-1} D_N$. As checks, at $N = 2$ this gives $\tilde{J}_{AB} = mD_2$, the coefficient in (14); deleting row and column A at $N = 3$ reproduces J in (38); and collapsing the $N-2$ identical bystanders reproduces the counting system (71) below. $\square$

Proof of Proposition 5.1. At $N = 3$, (24)–(25) give

$$d \log P_{M_A} = \frac{1}{2}(\nu_B + \nu_C + d\tau), \quad d \log P_{M_B} = \frac{1}{2}\nu_C - \nu_B, \quad d \log P_{M_C} = \frac{1}{2}\nu_B - \nu_C. \quad (69)$$

Also, $d \log \tilde{I}_A = \frac{m}{2} d\tau$, $d \log \tilde{I}_B = \nu_B$, and $d \log \tilde{I}_C = \nu_C$. The deviations of bilateral prices from the corresponding import indices are

$$\begin{aligned} dp_{AB} - d \log P_{M_A} &= \frac{1}{2}(\nu_B - \nu_C + d\tau), & dp_{AC} - d \log P_{M_A} &= \frac{1}{2}(\nu_C - \nu_B - d\tau), \\ dp_{BA} - d \log P_{M_B} &= -\frac{1}{2}\nu_C, & dp_{BC} - d \log P_{M_B} &= \frac{1}{2}\nu_C, \\ dp_{CA} - d \log P_{M_C} &= -\frac{1}{2}\nu_B, & dp_{CB} - d \log P_{M_C} &= \frac{1}{2}\nu_B. \end{aligned}$$

The share changes then follow from (27). With flow values $m/2$, (29) gives

$$\begin{aligned}\frac{2}{m} d \text{TB}_B &= (d \log s_{AB} + \frac{m}{2} d\tau - d\tau) + (d \log s_{CB} + \nu_C) - (d \log s_{BA} + \nu_B) - (d \log s_{BC} + \nu_B), \\ \frac{2}{m} d \text{TB}_C &= (d \log s_{AC} + \frac{m}{2} d\tau) + (d \log s_{BC} + \nu_B) - (d \log s_{CA} + \nu_C) - (d \log s_{CB} + \nu_C).\end{aligned}$$

For example, the coefficient on ν_B in $\frac{2}{m} d \text{TB}_B$ is

$$\underbrace{\frac{1}{2}[(1-\rho) + (1-\eta)\alpha_D]}_{d \log s_{AB}} + \underbrace{\frac{1}{2}[(1-\rho) + (1-\eta)\alpha_D]}_{d \log s_{CB}} + \underbrace{2(1-\eta)\alpha_D - 2}_{-d \log s_{BA} - d \log s_{BC} - 2\nu_B} = -(3\alpha_D(\eta-1) + \rho + 1) = -D_3.$$

Collecting the remaining coefficients gives (38); the replication package verifies the full collection symbolically. Inverting as in (39) gives (40). With $D_3 > 0$, the numerator for e_{AB} , $-(\rho + 3\rho_1^*)$, is negative and the numerator for e_{BC} , 2ρ , is positive for all admissible parameters. The bystander response satisfies $\text{sign}(d \log e_{AC}/d\tau) = \text{sign}(\rho - 3\rho_1^*)$. $\square$

Proof of Corollary 5.2. Setting $\rho = \eta = \sigma$ in $3\rho_1^* = 3[1 + \alpha_D(\sigma - 1) - \alpha_T(1 - \alpha_D)]$ gives

$$\rho_3^* - \sigma = \sigma(3\alpha_D - 1) + 3(1 - \alpha_D)(1 - \alpha_T).$$

If $\alpha_D \geq 1/3$, both terms are nonnegative, with equality in both only at $\alpha_D = 1/3$ and $\alpha_T = 1$. Reversal requires $\rho > \rho_3^*$, or equivalently $\sigma > \rho_3^*$, which is impossible whenever $\rho_3^* - \sigma \geq 0$. At $\alpha_D = 1/3$ and $\alpha_T = 3/4$, $\rho_3^* - \sigma = \frac{1}{2}$ and $D_3 = 3 \cdot \frac{1}{3}(\sigma - 1) + \sigma + 1 = 2\sigma$, so $d \log e_{AC}/d\tau = (\sigma - \rho_3^*)/(3D_3) = -1/(12\sigma)$. $\square$

Direct derivation of (37). The unilateral slopes can also be obtained by inverting the reduced two-equation system, without the eigenvalue argument. The equilibrium is unique by Proposition 4.2. Since the system is invariant to permutations of the $N - 2$ bystanders, the unique solution is also permutation-invariant, so all bystanders have the same response ν_C . The system therefore reduces to the conditions for B and one representative bystander. Equations (24)–(25) give

$$d \log P_{MA} = \frac{\nu_B + d\tau + (N-2)\nu_C}{N-1}, \quad d \log P_{MB} = \frac{(N-2)\nu_C}{N-1} - \nu_B, \quad d \log P_{MC} = \frac{\nu_B - 2\nu_C}{N-1}, \quad (70)$$

with $d \log \tilde{I}_A = \frac{m}{N-1} d\tau$, $d \log \tilde{I}_B = \nu_B$, and $d \log \tilde{I}_C = \nu_C$. The deviations of bilateral prices from the corresponding import indices are

$$\begin{aligned}dp_{AB} - d \log P_{MA} &= \frac{N-2}{N-1}(\nu_B + d\tau - \nu_C), & dp_{AC} - d \log P_{MA} &= \frac{1}{N-1}(\nu_C - \nu_B - d\tau), \\ dp_{BA} - d \log P_{MB} &= -\frac{N-2}{N-1}\nu_C, & dp_{BC} - d \log P_{MB} &= \frac{1}{N-1}\nu_C, \\ dp_{CA} - d \log P_{MC} &= -\frac{1}{N-1}[(N-3)\nu_C + \nu_B], & dp_{CB} - d \log P_{MC} &= \frac{1}{N-1}[(N-2)\nu_B - (N-3)\nu_C], \\ dp_{CC'} - d \log P_{MC} &= \frac{1}{N-1}(2\nu_C - \nu_B).\end{aligned}$$

Using (27) and flow values $m/(N-1)$, the two trade-balance conditions are

$$\begin{aligned}\frac{N-1}{m} d \text{TB}_B &= (d \log s_{AB} + \frac{m}{N-1} d\tau - d\tau) + (N-2)(d \log s_{CB} + \nu_C) - (d \log s_{BA} + \nu_B) - (N-2)(d \log s_{BC} + \nu_B) \\ \frac{N-1}{m} d \text{TB}_C &= (d \log s_{AC} + \frac{m}{N-1} d\tau) + (d \log s_{BC} + \nu_B) + (N-3)(d \log s_{C'C} + \nu_C) \\ &\quad - (d \log s_{CA} + \nu_C) - (d \log s_{CB} + \nu_C) - (N-3)(d \log s_{C'C'} + \nu_C).\end{aligned}$$

Collecting coefficients as in the proof of Proposition 5.1, and multiplying both rows by a further factor $N-1$ so that every coefficient is a multiple of D_N , gives the counting system

$$D_N \begin{pmatrix} -(N-1) & N-2 \\ 1 & -2 \end{pmatrix} \begin{pmatrix} \nu_B \\ \nu_C \end{pmatrix} = \begin{pmatrix} (N-2)\rho + \rho_1^* \\ \rho_1^* - \rho \end{pmatrix} d\tau, \quad D_N = N\alpha_D(\eta-1) + (N-2)\rho + 1; \quad (71)$$

the replication package verifies this collection symbolically. The right-hand side is $-\frac{(N-1)^2}{m}F$ with F as in (34). The counting matrix has determinant $2(N-1) - (N-2) = N$, so inversion gives (37), which reduces to (40) at $N=3$ and (15) at $N=2$.

Proof of Theorem 6.1. By Lemma 4.4 and (36), $\nu = \lambda_S \bar{t} \mathbf{1} + \lambda_D \tilde{t}$. For $t = d\tau \mathbf{e}_B$, $\bar{t} = d\tau/(N-1)$ and $\tilde{t}_C = -d\tau/(N-1)$, so $\nu_C = (\lambda_S - \lambda_D) d\tau/(N-1) = (\rho - N\rho_1^*) d\tau/(ND_N)$, which is (42). Under (20), $D_N > 0$ by (31), so $\text{sign}(d \log e_{AC}/d\tau) = \text{sign}(\rho - N\rho_1^*)$. The same substitution with $\tilde{t}_B = \frac{N-2}{N-1} d\tau$ gives $\nu_B = -[N\rho_1^* + (N-2)\rho] d\tau/(ND_N) < 0$ and $\nu_C - \nu_B = -\lambda_D d\tau = (N-1)\rho d\tau/(ND_N) > 0$, the remaining entries of (37). $\square$

Proof of Theorem 6.2. By Lemma 4.4, $d\nu_A^E = \lambda_S \bar{t}$ with symmetric weights $w_{A_j} = 1/(N-1)$. For $t = d\tau \mathbf{e}_B$, $\bar{t} = d\tau/(N-1)$, so $d\nu_A^E/d\tau = \lambda_S/(N-1) = -\rho_1^*/D_N$, which is (43); the terms in ρ do not enter because ρ appears only in λ_D . By (13), $\rho_1^* = \alpha_D \eta + (1-\alpha_D)(1-\alpha_T) > 0$ for $\alpha_D, \eta > 0$ and $\alpha_T \leq 1$. Since $D_N > 0$ under (20), the response is negative for every $N \geq 2$ and every admissible ρ . $\square$

Proof of Proposition 6.3. By linearity, $\nu = \sum_k t_k r^{(k)}$, where $r^{(k)}$ is the response to a unit tariff on partner k alone. By the symmetry of the partners, $r^{(k)}$ is the unilateral response (37) with B relabeled as k : its k -th entry is α and every other entry is β , which is (45), i.e., $\nu = Rt$ with $R = (\alpha - \beta)I + \beta \mathbf{1}\mathbf{1}'$. Since $\mathbf{1}'\mathbf{1} = N-1$, $R\mathbf{1} = [\alpha + (N-2)\beta]\mathbf{1}$, and for any v with $\mathbf{1}'v = 0$, $Rv = (\alpha - \beta)v$. Substituting α and β gives $\alpha + (N-2)\beta = \lambda_S$ and $\alpha - \beta = \lambda_D$, in agreement with (36). Writing $t = \bar{t} \mathbf{1} + \tilde{t}$ with $\mathbf{1}'\tilde{t} = 0$ gives $\nu = \lambda_S \bar{t} \mathbf{1} + \lambda_D \tilde{t}$. Averaging with weights $1/(N-1)$ gives $d\nu_A^E = \lambda_S \bar{t}$ because $\mathbf{1}'\tilde{t} = 0$, and subtracting gives the deviations. Finally, $d \log e_{jk} = \nu_k - \nu_j = \lambda_D(\tilde{t}_k - \tilde{t}_j) = \lambda_D(t_k - t_j)$. Under (20), $D_N > 0$ by Section 5.1, so $\lambda_S, \lambda_D < 0$. $\square$

Proof of Corollary 6.4. (i) From (46), $\nu_j - \nu_k = \lambda_D(t_j - t_k)$ with $\lambda_D < 0$. (ii) $\nu_j > 0$ iff $\lambda_S \bar{t} + \lambda_D(t_j - \bar{t}) > 0$. Substituting (36) and dividing by $(N-1)/D_N > 0$ gives $-\rho_1^* \bar{t} - \frac{\rho}{N}(t_j - \bar{t}) > 0$, i.e., $\frac{\rho}{N}(\bar{t} - t_j) > \rho_1^* \bar{t}$; dividing by $\bar{t} > 0$ gives the second form. The right-hand side $1 - N\rho_1^*/\rho$ is positive iff $\rho > N\rho_1^*$, and $t_j/\bar{t} \geq 0$, so the condition is infeasible otherwise. $\square$

Proof of Corollary 6.5. With $t_j = \tau$ on the k targets and zero otherwise, $\bar{t} = k\tau/(N-1)$, $\tilde{t}_B = \tau(N-1-k)/(N-1)$ for a target, and $\tilde{t}_C = -k\tau/(N-1)$ for a bystander. Substituting into (46), $\nu_C = \frac{k\tau}{N-1}(\lambda_S - \lambda_D) = \frac{k\tau}{ND_N}(\rho - N\rho_1^*)$, $\nu_B = \lambda_S \frac{k\tau}{N-1} + \lambda_D \frac{(N-1-k)\tau}{N-1}$, and $d\nu_A^E = \lambda_S k\tau/(N-1)$, which are (48). The sign of ν_C is that of $\rho - N\rho_1^*$ for every k . At $k = N-1$ there is no bystander and $\tilde{t} = 0$, giving (49). $\square$

Proof of Proposition 7.1. Let primes denote responses to the mirror shock $dt_{BA} = d\tau$. Relabeling $A \leftrightarrow B$ in (37) gives $d \log e'_{BA} = -[N\rho_1^* + (N-2)\rho]/(ND_N)$ and $d \log e'_{BC} = (\rho - N\rho_1^*)/(ND_N)$. Since $e_{AB} = 1/e_{BA}$ and $e_{AC} = e_{AB}e_{BC}$,

$$d \log e'_{AB} = \frac{N\rho_1^* + (N-2)\rho}{ND_N}, \quad d \log e'_{AC} = d \log e'_{AB} + d \log e'_{BC} = \frac{(N-1)\rho}{ND_N}.$$

By linearity, the war response is the sum of the original and mirror-shock responses:

$$d \log e_{AB}|^w = 0, \quad d \log e_{AC}|^w = \frac{\rho - N\rho_1^*}{ND_N} + \frac{(N-1)\rho}{ND_N} = \frac{\rho - \rho_1^*}{D_N}.$$

By symmetry between A and B , $d \log e_{BC}|^w = d \log e_{AC}|^w$. The war NEER is therefore $\frac{1}{N-1}[0 + (N-2)(\rho - \rho_1^*)/D_N]$. With $D_N > 0$, all three statements have the sign of $\rho - \rho_1^*$, independently of N . In the components of (55), B 's vector has $\bar{t}^{(B)} = d\tau/(N-1)$ and $\tilde{t}_C^{(B)} = -d\tau/(N-1)$, and its contribution to e_{AC} is $\lambda_D(t_C^{(B)} - t_A^{(B)}) = -\lambda_D d\tau = (N-1)\rho d\tau/(ND_N)$, which is (57). Substituting $\lambda_S = g_S/j_S$ and $\lambda_D = g_D/(Nj_S)$ from (35)–(36), the war response is $\frac{1}{N-1}[\lambda_S - \lambda_D]d\tau - \lambda_D d\tau = \frac{1}{N-1}[g_S/j_S - g_D/j_S]d\tau$, which is (58). $\square$

Proof of Proposition 7.2. Superpose the N tariff vectors using (55). A 's vector is uniform, $\bar{t}^{(A)} = d\tau$ and $\tilde{t}^{(A)} = 0$, contributing $\lambda_S d\tau$ to every $d \log e_{Aj}$. Partner j 's vector taxes only A : $\bar{t}^{(j)} = d\tau/(N-1)$, $\tilde{t}_A^{(j)} = \frac{N-2}{N-1}d\tau$, and $\tilde{t}_k^{(j)} = -d\tau/(N-1)$ for $k \neq A, j$. It contributes $-\lambda_S + (N-2)\lambda_D$ to $d \log e_{Aj} = -d \log e_{jA}$, and $\lambda_D(t_k^{(j)} - t_A^{(j)}) = -\lambda_D d\tau$ to each cross rate $d \log e_{Ak}$, $k \neq j$. Summing A 's own vector, partner j 's vector, and the $N-2$ other partners' vectors,

$$d \log e_{Aj} = \lambda_S d\tau - [\lambda_S + (N-2)\lambda_D] \frac{d\tau}{N-1} - (N-2)\lambda_D d\tau = \frac{N-2}{N-1}(\lambda_S - N\lambda_D) d\tau = \frac{(N-2)(\rho - \rho_1^*)}{D_N} d\tau.$$

The expression is the same for every j , so it equals the NEER response, and all cross rates between partners are zero. The same result follows by direct superposition of (49) with the relabeled unilateral responses in (37). $\square$

Proof of Proposition 6.6. From (10) and (6), only tradable prices move, so $d \log q_{Aj} = \nu_j + \alpha_T(d \log P_{T_j}^{\text{own}} - d \log P_{T_A}^{\text{own}})$, with $d \log P_{T_i}^{\text{own}} = (1 - \alpha_D)d \log P_{M_i}$. The indices in (70) are already expressed in own currency. Hence

$$d \log q_{AB} = \nu_B + m \left[\frac{(N-2)\nu_C}{N-1} - \nu_B - \frac{\nu_B + d\tau + (N-2)\nu_C}{N-1} \right] = \left(1 - \frac{mN}{N-1} \right) \nu_B - \frac{m}{N-1} d\tau.$$

The same calculation for $j = C$ gives (52), since the corresponding bracket reduces to $-\frac{N\nu_C + d\tau}{N-1}$. For a general tariff vector, $d \log P_{MA} = \frac{1}{N-1} \sum_j (\nu_j + t_j) = d\nu_A^E + \bar{t}$ and, since partners impose no

tariffs, $d \log P_{M_j} = \frac{1}{N-1} [\sum_{k \neq A} \nu_k - N \nu_j] = d\nu_A^E - \frac{N}{N-1} \nu_j$, so the bracket is $-\frac{N}{N-1} \nu_j - \bar{t}$, which gives (51); the unilateral case $\bar{t} = d\tau/(N-1)$ is (52). Setting $d \log q_{AC} = 0$ and substituting ν_C from (37) gives

$$[(N-1) - mN] \frac{\rho - N\rho_1^*}{N} = mD_N(\rho).$$

Because $D_N(\rho) = N\alpha_D(\eta-1) + (N-2)\rho + 1$ is linear in ρ , solving gives (53), using $(N-1) - mN - mN(N-2) = (N-1)(1-mN)$. If $m < 1/N$, the factor $(N-1) - mN$ is positive, and $D_N(\rho_q^*) > 0$ for $\eta \geq 1$. Hence $\rho_q^* > N\rho_1^*$, proving part (i). Averaging (52) over j and substituting (43) gives (54). Under (20), both terms are negative for $m < (N-1)/N$, proving part (ii). $\square$

Proof of Proposition 7.3. The result follows from (61). Total differentiation of market clearing gives $dp/dt_B \in (0, 1)$, and $M'_A < 0$ and $E'_j > 0$ then imply the stated signs of dq_B/dt_B and dq_C/dt_B . $\square$

Proof of Proposition B.1. Under the weights in (65), the bystanders remain interchangeable. By the same uniqueness and symmetry argument used in the direct derivation of (37) above, the system again reduces to two unknowns (ν_B, ν_C) . The corresponding flow values are $m\beta$, $m\gamma$, and $m\xi$, where $\beta = \kappa/(N-1)$, $\gamma = (1-\beta)/(N-2)$, and $\xi = (1-2\gamma)/(N-3)$. Write $\nu_B = b/N$ and $\nu_C = c/N$, holding $d\tau$ fixed, and expand the two equilibrium conditions in $1/N$ at fixed (κ, ρ) . To leading order, $\beta \rightarrow \kappa/N$, $(N-2)\gamma \rightarrow 1$, and

$$d \log P_{MA} = \frac{\kappa d\tau + c}{N} + O(N^{-2}), \quad d \log P_{MB} = \frac{c-b}{N} + O(N^{-2}), \quad d \log P_{MC} = O(N^{-2}).$$

Substituting into (27) and the flow sums, and multiplying the B and C conditions by N/m and $N(N-2)/m$, respectively, gives the limiting system

$$P(b-c) = -\kappa\rho d\tau, \quad P(2c-b) = \kappa(\rho - \rho_1^*) d\tau, \quad P \equiv \rho + \alpha_D(\eta-1) > 0 \quad \text{for } \eta \geq 1.$$

The first equation comes from the tariff term $\beta[(1-\rho)-1]d\tau = -\beta\rho d\tau$ and the relative share responses between B and the bystanders. The second comes from A 's diversion toward C net of C 's exposure to B , whose tariff coefficient is $\kappa[\rho-1+(1-\eta)\alpha_D+m] = \kappa(\rho-\rho_1^*)$. The limiting matrix $P \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}$ has determinant $P^2 > 0$, so the solution of the exact system converges to the solution of the limiting system. Adding the two equations gives $c = -\kappa\rho_1^* d\tau/P$. Since the NEER weights satisfy $w_{AB} = \beta = O(N^{-1})$ and $w_{AC} = \gamma$, with $(N-2)\gamma \rightarrow 1$,

$$N \frac{d\nu_A^E}{d\tau} = N[\beta\nu_B + (N-2)\gamma\nu_C]/d\tau \rightarrow \frac{c}{d\tau} = -\frac{\kappa\rho_1^*}{\rho + \alpha_D(\eta-1)}.$$

This equals $-\kappa \lim_N N\rho_1^*/D_N$ because $D_N/N \rightarrow P$. $\square$
